Introduction

Breast cancer is the disease which causes the greatest concern among women worldwide, with an estimated 1,152,161 new cases each year (1). The improvement of surgical techniques, neoadjuvant and adjuvant treatment enhance the survival time and recovery of these patients. As surgery is the first choice for the treatment of breast neoplasms reconstructive surgery has become an important procedure helping to reconstruct the mutilation after radical or conservative breast surgery. The objective of this article is to review the scientific literature and examine the available data regarding the role of physiotherapy in patients who undergo plastic reconstruction after oncological breast surgery, including suggestions on how physiotherapy could be applied in that population.

Materials and methods: Our review was obtained by searching the PubMed (National Library of Medicine, USA) and LILACS (Latin American and Caribbean Health Sciences) databases. Terms applied concerned physiotherapy and breast reconstructive surgery. The time of limit for our search was from 1995 until the present date.

Results: Fourteen articles were included in our review that matched our search criteria.

Conclusions: Physiotherapy is a field that still needs evidence based on daily routine and studies in the oncological physiotherapy field. Evaluation should be standardized and rehabilitation techniques used are empirical and should be researched in patients who undergo plastic reconstruction after breast surgery. The lack of post-surgery exercise protocols makes it difficult to analyse the patient's evolution and makes it a challenge to investigate the true role of physiotherapy in this population.

Keywords: Breast neoplasms; breast reconstruction; physiotherapy; rehabilitation

Introduction

Breast cancer is the most insidious oncological disease in women all over the world, with an estimate of 1,152,161 new cases each year (1). The improvement of surgical techniques, neoadjuvant and adjuvant treatment enhance the survival time and recovery of these patients (2–6). As surgery has been the first choice for the treatment of breast neoplasm (3,5) reconstructive procedures became more request, helping to reconstruct the mutilation after a radical or conservative breast treatment and enhance quality of live and physical function of these patients (7).

The most common modalities of reconstructive surgery are the use of expander and prosthesis based implants and the reconstruction using flaps tissues from other sites of the patient’s body (8). Both techniques are not risk free and sequelae like implant capsular contracture (9), swelling, pain, upper limb restriction (8), scar tissues and biomechanical muscular changes are not uncommon and sometimes are over evaluated and over treated.

As part of the rehabilitation regime, physiotherapy can assist in patient’s recovery after these reconstructive procedures, but the small number of specialized physiotherapy in the oncological field and lack of evidence
based techniques reduce the trust of the multidisciplinary team in physiotherapy professional. The objective of this article is to review the scientific literature and examine the available data regarding the role of the physiotherapy in patients underwent plastic reconstruction after oncological breast surgery.

**Search strategy and selection criteria**

A literature search was carried in October 2013 to identify studies of where physiotherapy had an active role (in pre and post-surgery assessment and with rehabilitation protocols) after oncological breast reconstructive surgery. Our review was obtained by search the PubMed (National Library of Medicine, USA) and LILACS (Latin American and Caribbean Health Sciences) databases using the following search themes: “Physiotherapy and breast reconstructive surgery”, “physiotherapy and prosthesis breast reconstruction”, “physiotherapy and expander breast reconstruction”. For the flaps surgery the search themes were separate by the flaps donor site: “physiotherapy after dorsal flap breast reconstructive surgery”, “recovery After dorsal flap reconstructive surgery”, “rehabilitation after dorsal flap breast reconstruction”, “physiotherapy after abdominal flap breast reconstructive surgery”, “recovery after abdominal flap reconstructive surgery”, “rehabilitation after abdominal flap breast reconstruction”, “physiotherapy after DIEP flap breast reconstructive surgery”, “recovery after DIEP flap reconstructive surgery” and “rehabilitation after DIEP flap breast reconstruction”. In an attempt to minimize the omission of potentially relevant clinical studies, we also reviewed the reference lists of included studies and relevant reviews for additional eligible articles. The time of limit for our search was from 1995 until the present date. Only papers in English were cited. Publications and citations were selected with the remit of this review. The articles were selected according to each subheading purpose in the review.

**Results**

Fourteen articles were included in our review that matches our search criteria. The results are in Figure 1. Breast cancer surgery and reconstructive surgery can lead to post-surgical sequelae and when surgery is concomitant, patients could be diagnosed with different kind of deficit of either axillary surgery or reconstructive surgery. These circumstances difficult the treatment and demand specialized physiotherapy and a multi and interdisciplinary team to manage and follow these patients.

**Implant based reconstructive surgery**

The implant-based reconstruction is the most common type of reconstruction after oncological breast surgery in many countries and institutions (7). In our clinical practice we are aware that oncological patients underwent reconstruction with expander or prosthesis have more difficult to start the rehabilitation protocol used for patients after breast surgery or axillary surgery without reconstruction, as the reconstruction could lead to more pain and restriction in range of motion of the upper limb (8). We recommend our patients who underwent these procedures to start a rehabilitation protocol in the first postoperative day. Patients and surgeons should be informed that most of exercises protocols found in literature are indicated to patients underwent breast or axillary surgery without concern in reconstruction (10).

After surgery, collateral effects like prosthesis encapsulation, post-surgery scar tissues, and breast edema are not infrequent (8,9). The indication of upper limb exercise and correction of postural antalgic position are advised. The use of massage therapy techniques, neuromuscular taping and manual lymphatic drainage are usual in the clinical practice, but there is a lack of protocols and studies that prove the efficacy in patients underwent oncological plastic surgery reconstruction with implants.

**Autologous based reconstructive surgery**

In patients who underwent autologous based reconstructive surgery, the evaluation should be made at preoperative day and that practice should be standard, to compare end evaluate the impairment and patients’ needs after surgery.

The post-operative evaluation should be executed in the range of 4 to 6 weeks. Postoperative condition of the patients and a correct communication between surgeon and physiotherapy should be taken in consideration prior to start any evaluation protocol. The use of the Kendall muscular evaluation (11) or manual muscle strength testing using the Medical Research Council (MRC) Scale (12) are broadly used by physiotherapist, but results tend to be subjective. We suggest the combination of digital dynamometers with the manual evaluation to give a more objective result (13). In literature the more used evaluation using an isokinetic machines (14-16), but they are expensive and most of
institutions and physiotherapy have no access to this machinery.

Several studies showed that patients underwent bi-pedicle transverse rectus abdominis myocutaneous (TRAM) flap had a decrease in strength during flexion movement six weeks after surgery. Kind et al. showed the modification in patients underwent unilateral pedicle TRAM flap finding a compensatory rotational strength pattern on the contra lateral side of surgery (14-17). These muscular changes tend to recovery between the three and six months after surgery (16,17). There are no studies that linked the abdominal strength changes with lower or upper back problems, even if it is well know that abdominal muscles is intrinsically related with the stabilization of the human body (18).

Patients underwent latissimus dorsi flap reconstruction had a reduction of rotator cuff and extension force 6 weeks after surgery, with a recovery in 3-6 months (19-23). Nevertheless that recovery did not reach the base lines find in pre-operative evaluation as demonstrated in the study of Forthomme et al. (22).

A small number of studies were found about deep inferior epigastric perforators (DIEP) procedure. All of them showed little reduction of wall strength in the first weeks after surgery when compared with TRAM flaps reconstruction (15,24-26). Nevertheless, the indication of a correct posture after surgery should be given to all patients, as the pain and dyskinesia in the abdominal area could affect the correct imbalance in walk or execute daily activities in the first months. Patients who are more susceptible to venous congestion and fat necrosis (27) should be identified, so any rehabilitation procedure should be carefully discussed among the surgeon and patient.

The literature shows a small probability of embolic events or respiratory complications after TRAM and DIEP surgeries (28). Respiratory physiotherapy should be a concern in the first postoperative day as patients underwent breast reconstruction with abdominal flap tends to be long time in the operation room, bed immobilization and pain in abdominal area. The use of respiratory exercises can help prevent atelectasis and mucus mobilization and early ambulation deep venous thrombosis. Patients should be inform on how assume a correct posture, mobilization from bed to stand position, to walk, and seat (29,30). It's important to correct any kind of antalgic position after surgery that

could evoke muscular contractions and more pain.

As part of the assessment, a validated questionnaire (10,31) could be used to assess the results of the physiotherapy, quality of life and any emotional distress. The physiotherapy must collaborate with the multidisciplinary team, as the collateral effects of reconstructive surgery could be more than only mechanical or physical (32).

During our review, there were no studies regards exercises or postural education protocols aimed to patients underwent TRAM, DIEP or latissimus dorsi procedures. The suggestion of postural global reeducation (33,34), Pilates (35-37), CORE exercise (38) and upper limb exercise (10) could be part of the rehabilitation protocol but these techniques need to be studied and researched in patients underwent reconstructive surgery after breast cancer surgery.

Conclusions

Physiotherapy is a field that still needs evidence based in the daily routine and studies in the breast oncological physiotherapy field are warranted. Evaluation should be standardized. Rehabilitation techniques used are empirical and should be researched in patients underwent plastic reconstruction after breast surgery. The lack of postsurgery exercise protocols difficult the analyses of patient’s evolution and making challenging to prove the real role of the physiotherapy in this population.
